Abstract. This paper introduces a new static data dependence constraint, called dependence difference inequality, which can deal with coupled subscripts for multi-dimensional array references. Unlike direction vectors, dependence difference inequalities are related to not only the iteration space for a loop program but also the operation distance between two operations. They are more strict than other methods, and can act as additional constraints to each variable in a linear system on their own or with others. As a result, the solution space for a linear system can be compressed heavily. So long as dependence difference inequalities do not satisfy simultaneously, the loop can be software-pipelined with any initiation interval even if there exists a data dependence between two operations. Meanwhile, by replacing direction vectors with dependence difference inequalities some conservative estimations made by other traditional data dependence analysis approaches can be eliminated.

1 Introduction

Data dependence analysis plays an important role in automatic detection of implicit parallelism in programs written in conventional sequential languages. Dependence analysis techniques estimate, at compile-time, the run-time interactions between different operations or between different instances of the same operation [1].

It is at the core of data dependence analysis strategies to estimate data dependence between two operations in which multi-dimensional array references are involved. General speaking, the question of whether multi-dimensional array references with coupled linear subscripts can be parallelized depends upon the resolution of multi-dimensional array aliases. The resolution of multi-dimensional array aliases is to ascertain whether or not the two references to the same multi-dimensional array within a general [nested] loop can refer to the same element of that multi-dimensional array [2].

The paper focuses on a new data dependence analysis technique for an interlaced inner and outer loop software pipelining algorithm. Our approach, called dependence difference inequalities, can deal with coupled subscripts for multi-dimensional array references statically. This paper is organized as follows. Section 2 introduces related work and background, while Section 3 discusses dependence difference inequalities. Section 4 draws a conclusion.
2 Related Work and Background

This section introduces a novel software pipelining algorithm and gives a brief description of data dependence analysis techniques.

2.1 Interlaced Inner and Outer Loop Software Pipelining Algorithm

Software pipelining algorithms currently pursued in the world exploit the instruction-level parallelism of loop program by overlapping the operations of different loop bodies. Using software pipelining, a loop is transformed into a semantics-equivalent program consisting of a new loop, a prologue and an epilogue.

Several effective software pipelining algorithms have been presented to optimize innermost loops, such as Modulo Scheduling [3] and GURPR* [4]. In most cases, however, actual programs always contain nested loops. Optimization performance of existed algorithms is fairly insufficient when they are used to optimize nested loop programs, so it is the key to develop new algorithms that can efficiently optimize these nested loop programs.

Interlaced inner and outer Loop Software Pipelining (ILSP) is an efficient algorithm that can optimize operations in nested loops with various loop structures. In order to make the ILSP algorithm work efficiently and correctly, corresponding control mechanism, which combines software pipelining techniques with several hardware features, is introduced in [5]. In [6], Rong and his co-operators introduces a single-dimension software pipelining algorithm, which can be outlined as a brief version of the ILSP algorithm. Their algorithm chooses the most profitable loop level in the loop nest and software-pipelines it, which has been implemented as a tool set on an IA-64 Itanium workstation.

The ILSP algorithm is different from any traditional software pipelining algorithms of nested loops. ILSP does not execute the nested loops in the traditional sequence of completing the inner loop first and then executing the outer loop. It breaks the boundary of the different loop bodies of the nested loop, and can overlap the inner loop bodies of different outer loop bodies. Thus, ILSP makes it possible to optimize nested loops with various loop structures.

Consider the nested loop example as shown in Fig. 1. It can be performed well using the ILSP, as shown in Table 1.

By the example, we can describe the basic principle of the ILSP as follows. The ILSP is a software pipelining algorithm that is suitable for the nested loops with various loop structures. When each loop body of the nested loops is pipelined, the ILSP pipelines the nested loop as if the inner loops of this loop were executed only once. Whenever a new execution pattern made up of operations of an inner loop appears, in other words, the inner loop becomes active, the execution of the outer loop will be temporarily stopped. At this moment the software pipelining of the inner loop will be continuously executed until it is ready to enter its epilogue stage and to return to its outer loop or until another inner loop becomes active. When the inner loop begins to execute, the outer loop gives all its function units to the inner loop, and when the inner loop is completed, it will give all function units back to the outer loop, and the execution of the outer loop will be continued.
In one word, the foundation of the ILSP algorithm is to perform the nested loops as a whole. In order to form an effective pipeline along different loop bodies of the nested loop, it is very necessary to feed it with enough operations. A data dependence analysis approach has to meet the demand.

```plaintext
for (i=1; i<=n; i++) {
    op1;
    for (j=1; j<=m; j++) {
        op2;
        op3;
        op4;
    }
    op5;
}
```

### 2.2 Data Dependence Analysis

Suppose op1 and op2 be two operations within a n-nested loop which refer to a m-dimensional array simultaneously. Each iteration of the loop is identified by an iteration vector whose elements are the values of the iteration variables for that iteration. We have

**Definition 1.** Let op1(\(i\)) and op2(\(j\)) respectively denote the instance of the operation op1 during the iteration \(i = (i_1, i_2, ..., i_n)\) and that of the operation op2 during the iteration \(j = (j_1, j_2, ..., j_n)\). There exists a partial order between the two operation
instances, \( \text{op}_1(\bar{i}) < \text{op}_2(\bar{j}) \), if (a) for given an \( r \) where \( 1 \leq r \leq \min\{m, n\} \), \( i_r = j_r \) and \( i_k \leq j_k \) \((1 \leq k < r)\) hold, or (b) for \( m \leq n \), \( i_r = j_r \) \((1 \leq r \leq m)\) holds.

Practically an partial order \( \text{op}_1(\bar{i}) < \text{op}_2(\bar{j}) \) means that \( \text{op}_1(\bar{i}) \) precedes \( \text{op}_2(\bar{j}) \). If the instance of the operation \( \text{op}_1(\bar{i}) \) uses the element of the array defined first by the instance of the operation \( \text{op}_2(\bar{j}) \), then \( \text{op}_2(\bar{j}) \) is true-dependent or write-read-dependent on \( \text{op}_1(\bar{i}) \). If the instance of the operation \( \text{op}_2(\bar{j}) \) defines the element of the array used first by the instance of the operation \( \text{op}_1(\bar{i}) \), then \( \text{op}_2(\bar{j}) \) is anti-dependent or read-write-dependent on \( \text{op}_1(\bar{i}) \). If the instance of the operation \( \text{op}_2(\bar{j}) \) redefines the element of the array defined first by the instance of the operation \( \text{op}_1(\bar{i}) \), then \( \text{op}_2(\bar{j}) \) is output-dependent or write-write-dependent on \( \text{op}_1(\bar{i}) \).

In general, suppose the \( n \)-nested loop have linear lower bounds and upper bounds, \( f_i \) denote the lower bound function for the \( k \)-th level nested loop, and \( g_i \) the upper bound function. It is obvious that \( f_i \leq i_0, j_k \leq g_n, 1 \leq k \leq n \) hold simultaneously. By replacing \( i_k \) with \( x_{2k-1} \) and \( j_k \) with \( x_{2k} \), the problem mathematically can be reduced to that of checking whether or not a system of \( m \) linear equations with \( 2n \) unknown variables has a simultaneous integer solution, which satisfies the constraints for each variable in the system. The \( m \) linear equations in the system can be written as

\[
\begin{align*}
& a_{i,0} + a_{i,1}x_{1} + a_{i,2}x_{2} + \ldots + a_{i,2n}x_{2n} = 0 \\
& a_{2,0} + a_{2,1}x_{1} + a_{2,2}x_{2} + \ldots + a_{2,2n}x_{2n} = 0 \\
& \vdots \\
& a_{m,0} + a_{m,1}x_{1} + a_{m,2}x_{2} + \ldots + a_{m,2n}x_{2n} = 0
\end{align*}
\]

where each \( a_{i,j} \) is a constant integer for \( 1 \leq i \leq m \) and \( 1 \leq j \leq 2n \). \( i = (x_{1}, x_{3}, \ldots, x_{2n-1}) \) and \( j = (x_{2}, x_{4}, \ldots, x_{2n}) \) denote two iteration vectors, \( \text{op}_1(\bar{i}) \) and \( \text{op}_2(\bar{j}) \), respectively. Constraints to each variable in Eq. (1) can be represented as

\[
\begin{align*}
& P_{i,0} + \sum_{r=1}^{\bar{i}} P_{r,x_{2r-1}} - f_i(x_{1}, x_{3}, \ldots, x_{2\bar{i}-1}) \leq x_{2\bar{i}-1} \leq g_i(x_{1}, x_{3}, \ldots, x_{2\bar{i}-1}) = Q_{i,0} + \sum_{r=1}^{\bar{i}} Q_{r,x_{2r-1}}, 2 \leq k \leq n & (2) \\
& P_{i,0} + \sum_{r=1}^{\bar{i}} P_{r,x_{2r}} = f_i(x_{2}, x_{4}, \ldots, x_{2\bar{i}-2}) \leq x_{2\bar{i}-2} \leq g_i(x_{2}, x_{4}, \ldots, x_{2\bar{i}-2}) = Q_{i,0} + \sum_{r=1}^{\bar{i}} Q_{r,x_{2r}}, 2 \leq k \leq n
\end{align*}
\]

where \( P_{r,0}, Q_{r,0}, P_{r,\bar{i}}, Q_{r,\bar{i}} \) are constant integers for \( 1 \leq r \leq n \). If each of \( P_{r,\bar{i}} \) and \( Q_{r,\bar{i}} \) is zero, the Eq. (2) will be reduced to

\[
P_{i,0} \leq x_{2\bar{i}-1, x_{2\bar{i}}} \leq Q_{i,0}, 1 \leq k \leq n.
\]

That is, the bounds for each variables are constants.

**Definition 2.** A vector of the form \( e = (e_1, e_2, \ldots, e_n) \) is termed a direction vector from \( \text{op}_1(\bar{i}) \) to \( \text{op}_2(\bar{j}) \) if for \( 1 \leq k \leq d \), \( i_k \leq j_k \), i.e., the relation \( e_k \) is defined by

\[
e_k = \begin{cases} 
< & \text{if } i_k < j_k \\
= & \text{if } i_k = j_k \\
> & \text{if } i_k > j_k 
\end{cases} \text{ for any one of } \{<,=,>\}
\]
There are several well-known data dependence analysis algorithms exploited for practical parallelizing compilers. The Banerjee Inequalities can handle one linear equation under the bounds of Eq. (3) and Eq. (4), and the Banerjee Algorithm can deal with one linear equation under the bounds of Eq. (2) and Eq. (4) [7]. When applied to practical cases, the Banerjee Test (the Banerjee Inequalities and the Banerjee Algorithm) may lose accuracy. The I Test and the Direction Vector I Test are a combination of the Banerjee inequalities and the GCD Test [8] [9]. They determine integer solutions for a linear equation with constant bounds and given direction vectors. The Lambda Test extends the Banerjee Inequalities to allow m linear equations in Eq. (1) under the constraints of Eq. (3) and Eq. (4) to be tested simultaneously [10]. And the Generalized Lambda Test allows m linear equations in Eq. (1) under the constraints of Eq. (2) and Eq. (4) to be tested simultaneously [2]. More precise results can be obtained by judging the consistency of a linear system of equations and inequalities inexpensively.

All of above data dependence analysis methods, however, are exploited for general parallelizing compilers, and they ignore the fact that the software pipelining technique per se has an impact on instruction-level parallelism. The next section will prove that for instruction-level parallelizing compilers more interesting results can be achieved under additional constraints of dependence difference inequalities.

3 Dependence Difference Inequalities

This section introduces a kind of additional constraints, called dependence difference inequalities, for software pipelining techniques. Under these additional constraints the solution space for a linear system can be compressed heavily.

3.1 Relationship between Software Pipelining and Data Dependence

In general, the ILSP algorithm overlaps adjacent iterations of a nested loop program. The initiation interval of these adjacent iterations, denoted by II, is only restricted by resource limit, denoted by II_res, and sequential semantics of the loop program, denoted by II_sem, i.e., II = max{II_res, II_sem}. For the sake of clarity the paper only concentrates on II_sem since II_res can always be released by using more function units.

Definition 3. Let op1 and op2 be two operations of a loop program. The number of operations between op1 and op2 plus 1 is referred to as operation distance, denoted by dis(op1, op2).

Definition 4. If op2(j) is dependent on op1(i), i = (x1, x3, ..., x2n−1) and j = (x2, x4, ..., x2n), then i − j = (x1 − x2, x3 − x4, ..., x2n−1 − x2n) is referred to as dependence difference vector, denoted by dif(op1, op2), and i_k − j_k = x2k−1 − x2k is referred to as the dependence difference in the k-th level nested loop, denoted by dif_k(op1, op2). If dif_k(op1, op2) = 0 then op2(j) is intra-loop-dependent on op1(i) otherwise inter-loop-dependent.

For the ILSP algorithm intra-loop-dependences have no impact on II_sem but those inter-loop-dependences may make a strong impact on II_sem.
Lemma 1 [11]. Let \( op_1 \) and \( op_2 \) be two operations, both belonging to the same \( k \)-th level nested loop. If \( 0 < \text{dif}(op_1, op_2) \leq \text{dis}(op_1, op_2) \) does not hold, then the loop program can be software-pipelined with \( II_{sem} = 1 \).

Lemma 1 shows that the loop program can not be software-pipelined with \( II_{sem} = 1 \) when \( 0 < \text{dif}(op_1, op_2) \leq \text{dis}(op_1, op_2) \) holds. However, it does not imply that the loop program can not be software-pipelined with a greater one.

Definition 5. An inequality of the form \( 1 \leq \text{dif}(op_1, op_2) \leq \text{dis}(op_1, op_2) \) is termed a dependence difference inequality for \( 1 \leq k \leq n \).

Theorem 1 [11]. Let \( op_1 \) and \( op_2 \) be two operations, both belonging to the same \( n \)-nested loop program whose loop labels are denoted by \( L_1, L_2, \ldots, L_n \) in turn. The loop can be software-pipelined with any value of initiation interval if the following dependence difference inequalities

\[
1 \leq \text{dif}(op_1, op_2) \leq \text{dis}(op_1, op_2), \ 1 \leq k \leq n, \tag{5}
\]

do not satisfy simultaneously.

Theorem 1 implies that dependence difference inequalities can act as, on their own or with other constraints, additional constraints to each variable in a linear system. If there does not exist any integer solution for the linear system under these constraints, the loop can be software-pipelined with \( II_{sem} = 1 \) even if a data dependence between two operations exists.

3.2 Dependence Difference Inequalities vs. Direction Vectors

In general, a direction vector \( e = (e_1, e_2, \ldots, e_n) \) bounds the solution space for a linear system with \( i_k < j_k \) or \( i_k > j_k \) for \( 1 \leq k \leq n \). \( i_k = j_k \) means two operations are intra-loop-dependent on each other, and thus the dependence can be ignored when the loop is software-pipelined by the ILSP algorithm.

Suppose \( i_k > j_k \). When using a direction vector as a constraint we have \( f_k(x_2, x_4, \ldots, x_{2n}) \leq j_k < i_k \leq g(x_1, x_3, \ldots, x_{2n-1}) \), i.e.,

\[
1 \leq i_k - j_k \leq g(x_1, x_3, \ldots, x_{2n-1}) - f_k(x_2, x_4, \ldots, x_{2n}). \tag{6}
\]

On the other hand, by using dependence difference inequalities as constraints we have

\[
1 \leq i_k - j_k \leq \text{dis}(op_1, op_2). \tag{7}
\]

It is shown that dependence difference inequalities are more strict than direction vectors since in most cases \( g(x_1, x_3, \ldots, x_{2n-1}) - f_k(x_2, x_4, \ldots, x_{2n}) \), as an iteration counter, is far greater than \( \text{dis}(op_1, op_2) \). In one word, these dependence difference inequality constraints make our data dependence analysis algorithm more powerful.

Table 2 gives a practical loop example where \( op_2 \) is anti-dependent on \( op_1 \) and \( \text{dis}(op_1, op_2) = 3 \). The corresponding data dependence equation of the loop program is \( 2i_1 + 1 = j_1 \), i.e., \( 2i_1 - j_1 = -1 \). Because \( \gcd(2, 1) = 1 \), the GCD Test draws a conclusion that \( op_1 \) is dependent on \( op_2 \) and the loop can not be parallelized. On the other hand, it can be derived that \( -90 \leq 2i_1 - j_1 \leq 195 \) from \( 5 \leq i_1, j_1 \leq 100 \), namely, \( -90 \leq -1 \leq 195 \), which makes the Banerjee Test also draws a conclusion that the loop can not be parallelized. Furthermore, when a direction vector \( i_1 < j_1 \) is applied we first
have \(-95 \leq i_1 - j_1 \leq -1\), and second \(-106 \leq i_1 - j_1 \leq -6\) from \(i_1 - j_1 = -i_1 - 1\). The Banerjee Test still draws the same conclusion since the interaction of the solution spaces for the two inequalities is not empty.

Table 2. Dependence difference inequalities are more strict than direction vectors

<table>
<thead>
<tr>
<th>Clock</th>
<th>Iteration</th>
</tr>
</thead>
<tbody>
<tr>
<td>(i = 5)</td>
<td>(i = 6)</td>
</tr>
<tr>
<td>2</td>
<td>(Y = X + 5);</td>
</tr>
<tr>
<td>3</td>
<td>(Z = Y \times 3);</td>
</tr>
</tbody>
</table>

When replacing the direction vector with a dependence difference inequality, we can clearly find the interaction of the solution spaces for the two inequalities, \(1 \leq i_1 - j_1 \leq \text{dis}(\text{op}_1, \text{op}_2) = 3\) and \(-106 \leq i_1 - j_1 \leq -6\), is empty. Thus our data dependence analysis algorithm determines that the loop can be paralleled, as shown in Table 2.

4 Conclusion

This paper has presented a new static data dependence analysis approach, called dependence difference inequality, for our software pipelining algorithm ILSP for nested loops. Our data dependence analysis approach can deal with coupled subscripts for multi-dimensional array references statically.

Conceptually, unlike a direction vector, a dependence difference inequality is not only related to the iteration space for a loop program but also related to the operation distance between two operations. Dependence difference inequalities can act as additional constraints to each variable in a linear system on their own or with other constraints, such as direction vectors. They are more strict than a direction vector and make our data dependence analysis algorithm more powerful. As a result, the solution space for the linear system can be compressed heavily.

Under constraints of dependence difference inequalities, so long as these inequalities do not satisfy simultaneously, the loop can be software-pipelined with any value of initiation interval even though there exists a data dependence between two operations. The paper has also shown that some conservative estimations made by other traditional data dependence analysis approaches can be eliminated by replacing a direction vector with a dependence difference inequality.

Further experimental results are reported in [12]. On the other hand, a dynamic data dependence analysis approach is presented in [13], which can work with this method together to coping with data dependencies for software pipelining.
