Abstract: The GMPLS standardization is paving the way for new configurable Traffic Engineering (TE) policies and new survivability schemes for transport networks. In this context, a centralized Path Computation System (PCS) has been implemented, suited for transport networks with a GMPLS control plane. After a brief description of the requirements for a PCS in a GMPLS network, some design issues for the proposed implementation are drawn, with particular emphasis on the centralized approach and on the strategies for achieving the connection survivability. Some results of an intensive testing campaign are shown for the validation of the design choices.

1. INTRODUCTION

The international standardization committees (e.g. ITU-T, OIF and IETF) are all converging in the design of an integrated network with a common Generalized Multi-Protocol Label Switching (GMPLS) control plane. GMPLS will manage all the network data planes [1, 2], providing the required automation in the computation, the setup and the recovery of circuits for next-generation Automatically Switched Optical Network (ASON).

GMPLS is an extension to devices capable of performing switching in time, wavelength and space domains of the MPLS control plane architecture. The core GMPLS architecture is based on a set of extensions to protocols for routing (e.g. OSPF and IS-IS) and signalling (e.g. RSVP), just available in IP networks. Moreover, other signalling protocols have been proposed (e.g. LDP, CR-LDP) and a new link management protocol (i.e. LMP) has been designed.
from scratch in order to relate properly the de-coupling between Data Plane and Control Plane. From a routing perspective, the GMPLS extensions provide new information for circuit computation and they enable configurable Traffic Engineering (TE) policies and new recovery strategies. In such a context, this paper takes aim at describing the implementation of a centralized Path Computation System (PCS) suited for transport networks with a GMPLS control plane. In details, Sec. 2 is focused on the requirements for the PCS in a centralized GMPLS network scenario. In Sec. 3 the design issues for the proposed implementation are drawn, with particular emphasis on the centralized approach and on the strategies for achieving the connection survivability. Some results of an intensive testing campaign are shown in Sec. 4 while conclusions and future directions are given in Sec. 5.

2. REQUIREMENTS FOR A GMPLS PCS

Within GMPLS standardization, the main focus is on protocols objects and mechanisms, while only high level requirements are proposed for traffic engineering (TE) and survivability. In the GMPLS context, a set of properties is assigned to each link for routing purposes (e.g. TE metric, available/used bandwidths, resource colours, SRLG list, inherent protections, etc.), transforming a traditional links in a Traffic Engineering link (TE-link). A GMPLS path calculator is expected to return Label Switched Paths (LSPs), i.e. sequences of nodes, TE-links and – in case – labels, which try to match some constraints derived from the TE information above. Once an LSP is computed, it describes univocally a unidirectional or bi-directional connection between a source and a destination node.

The standard Shortest Path First – SPF – algorithms [3] are not suited for such a computation, since they cumulate only the standard link metric along the path. A modified SPF algorithm is needed, called Constraint-based Shortest Path First (CSPF) and routes should be the shortest among those which satisfy the required set of constraints [4]. Another important issue, raised by the great traffic amount carried on a LSP, is the connection survivability after a fault. The solution for this problem depends on the recovery strategy implemented in the network. New recovery strategies are enabled by the GMPLS control plane according to the overall taxonomy sketched in Figure 1 (ref. [5–8] for details). Span level strategies are prone to waste resources in the network, because of the sub-optimality of the resulting backup paths; whereas end-to-end recovery strategies are more efficient. Moreover, restoration fits better the dynamical assignment/release of the network resources with respect to protection; but, in case of a fault, a higher blocking probability for the restoring traffic might be experimented, due to the failure handling by control plane mechanisms instead of hardware ones (e.g. detection, notification and miti-
A common requirement for all the recovery strategies shown above is the disjointness between the resources (links or nodes) used by the primary route and by its backup. This is needed to minimize the blocking probability of the dynamical recovery action in case of fault. In the GMPLS architecture different levels of disjointness for LSPs are defined [4, 8]:

- **node**, in which different nodes (and different links) are crossed by the primary-backup pair of LSPs;
- **link**, in which only different links are crossed by the two LSPs;
- **SRLG**, in which the Shared Risk Link Group lists of the two LSPs have no intersection.

### 3. DESIGN ISSUES FOR A GMPLS PCS

In the GMPLS architecture the specification for PCS is considered implementation dependent and no preference can be derived by the standards on the choice of a centralised or a distributed implementation, besides of the intrinsic distributed approach of the GMPLS control plane. The architectural choice we made in the context of the TANGO project is for the implementation of the PCS module inside a centralized network manager (NM). This solution promises to be the most effective for a full and flexible handling of traffic engineering and survivability into the network, particularly when these requirements need to be extended to a multi-area (or multi-domain) scenario. In our implementation the PCS acts as a path computation server for the GMPLS network (ref. Figure 2), receiving from the GMPLS Network Elements (NE) the topology information and the computation requests across a single- or multi-area/AS. The LSPs computed by PCS (if any) are communicated to the ingress GMPLS NE, triggering a standard GMPLS signalling session (e.g. via G.RSVP-TE). The communications between the NM and the NEs are carried out by means of COPS protocol with proper extensions (ref. [9] for details).
We based our routing engine on an implementation of the Dijkstra SPF algorithm, properly modified with a TE-constraints validation step for handling Constrained SPF computations. One of these constraint validations is the check on the bandwidth availability of the candidate link. Moreover, in order to let the algorithm converge towards an optimal SPF solution (e.g. between those which satisfies the required TE-constraints), the metric we chose to minimize during computation is bandwidth-dependent, according to the equation:

$$\text{link\_weight} = \text{std\_metric} + \text{TE\_metric} + F(\text{avail\_bw})$$  \hspace{1cm} (1)

where \text{std\_metric} is the standard OSPF link metric, \text{TE\_metric} is the GMPLS metric for TE purposes, \text{avail\_bw} is the available bandwidth on the TE-link and \(F(\alpha)\) is a proper Traffic Engineering function designed for balancing bandwidth consumption on the links.

The main feature of our PCS is in the processing of LSP requests with survivability requirements. Based on the recovery taxonomy at path-level and on the requirements shown in Sec. 2, we identified three Classes of Recovery (CoR) for the LSP requests, distinguishing the survivability of the connections according to an Olympic model:

- \textit{Gold}, when the lowest blocking probability for the recovery and the fastest reaction times (e.g. around 50ms) are required. This CoR applies to the protection strategies; it implies the computation of a pair of maximally disjoint paths in order to guarantee the total resource redundancy and uncorrelation.
• **Silver**, when fast reaction times (e.g. less than 1 s) are required. This CoR applies to Fast Restoration strategies; it implies the computation of a pair of disjoint paths in order to guarantee a level of resource uncorrelation.

• **Bronze**, when reaction times around 1 s are acceptable. This CoR applies to On-the-fly restoration strategies; it implies the computation of an optimal worker path when the request is received and the computation of an optimal backup one at failure occurrence.

In this model are not included *Unprotected* LSP, with no request for survivability of the carried traffic (e.g. preemptable or best-effort traffic). The bronze service is the slowest approach because of the time spent for failure detection, localisation, notification and mitigation. The silver service is sub-optimal as well, because the backup paths do not take into account any modification of the network load/topology occurred in the meanwhile. In this case, we chose to compute the backup LSP trying to satisfy the required link/node disjointness, but with no guarantee for success and for optimality (i.e. the resulting backup might not be maximally disjoint w.r.t its primary and the pair might not have the cumulative shortest cost in the network). For this kind of computation we used the Two Step Approach (TSA) algorithm, based on two Dijkstra SPF runs [3] and on a simple temporary network transformation for avoiding links/nodes of the worker path. The gold service is the most exacting in terms of optimality of the computation, because a least cost pair of disjoint paths is required, providing that it is also the maximally disjoint pair in the network. Many algorithms have been proposed in literature for such a computation [5, 10, 11], most of them in the general context of the K-shortest path theme. We focused on the work by R. Bhandari because it promised lower theoretical complexity w.r.t. other algorithms (e.g. the famous Suurballe’s one), when only $K = 2$ shortest paths are searched. The Bhandari’s algorithm implemented in this work is the optimal counterpart to the sub-optimality of TSA one. However this optimality is paid for a higher complexity introduced by the required network transformation, by a modified SPF running also on negative graphs and by an interlacing/re-ordering procedure for the final paths.

4. **PERFORMANCE STUDIES**

This section is aimed at highlighting the performance of the routing scheme adopted when computing a pair of maximally disjoint shortest paths with respect to links or to nodes. Measures have been collected on different topologies with increasing meshing degrees (ref. Figure 3), ranging from an interconnected rings topology derived from the Interoute I-21 network (meshing degree 3.14) to a number of Manhattan topologies variously connected (meshing degrees from 3.43 to 6.84).
Figure 3. Generic lattice topologies: (a) simple Manhattan; (b) half-meshed Manhattan; (c) meshed Manhattan.

All these topologies have been modelled with generic nodes, configurable as fully connectable SDH 4/4 Cross-Connects. Adjacent nodes have been connected by a bi-directional TE-link with random values for its TE-information (e.g. TE metric, available/used bandwidths, resource colours, SRLG list, etc.). All the TE-links have been configured with 4 STM-64 ports VC4-multiplexed; so, a maximum of 256 allocable labels has been obtained in each adjacency. The computational environment for all the tests has been based on a Pentium III 800MHz PC with Linux RedHat 7.1 OS. A large number of bi-directional LSP computations (req_path) have been requested on each topology (e.g. up to a connection request from each node towards all the others), trying to test the algorithms in an overloading condition and observing: (a) the number of computed LSPs (comp_path); (b) the number of totally link-/node-disjoint pairs of LSPs (disjoint); (c) the mean computation time for each LSP request (time).

The overall performance of the two types of algorithms has been measured by evaluating a Global Performance Factor (GPF), defined as:

$$GPF = \frac{\text{disjoint}}{\text{req.path}} \cdot \frac{\text{comp.path}}{\text{req.path}}$$  \hspace{1cm} (2)

The first term is related to the algorithm’s effectiveness in creating maximally disjoint paths while the latter represents the algorithm’s effectiveness in computing valid paths, according to the resource availability on TE-links. This latter term has no effect on GPF in case of a theoretical infinite resource availability. In Figure 3-a and Figure 3-b the GPF is drawn at the different meshing degrees, showing a mean higher performance for the Bhandari’s algorithm w.r.t. the TSA one (+0.57% for link- and +2.79% for node-disjointness). The higher complexity in Bhandari’s algorithm is responsible for an increase in mean computation times for each LSP request (+3.59% for link and +4.14% for node-disjointness) as shown in Figure 5 only for the link because the two trends are similar. This is due to the higher complexity introduced by Bhandari’s algorithm (e.g. the graph transformation, the modified SPF for negative graphs and, last but not least, the interlacing/re-ordering procedure for the fi-
nal paths). Results highlight an alignment between the Bhandari’s algorithm and the TSA when meshing degree increases. This is due to the higher resource availability in the network. However, this trend is strictly related to the variance of the TE-metric values for the TE-links; actually, other tests, not presented here, showed that the more TE-metrics were different between TE-links, the more the Bhandari’s algorithm achieved the best performance w.r.t the TSA one. Moreover, these results confirmed that node disjointness proves to be a more exacting requirement than the link one, whatever algorithm is used (e.g., Bhandari’s or TSA). In fact, link-disjoint algorithms provided generally a higher number of disjoined paths. The higher number of path computation failures at lower meshing degrees (e.g. interconnected rings and simple Manhattan) is strictly related to the resource availability on TE-links. In case of the TSA algorithm, this issue merges with the intrinsic sub-optimality of this algorithm. This assertion is supported by the results obtained for the 8-interconnected rings and the Manhattan topologies in case of theoretical infi-

nite resource availability (ref. Figure 6). We observed that only the Bhandari’s algorithm provided disjoint paths for every request, with an acceptable increase of the main computation time.

5. CONCLUDING REMARKS

This paper describes the implementation of a centralized Path Computation System (PCS) suited for transport networks with a GMPLS control plane. The requirements and the major design issues for the PCS are drawn, with particular emphasis on the centralized approach and on the strategies for achieving the connection survivability. Some results of an intensive testing campaign are given in support of the design choices w.r.t. survivability. Other tests are going to be completed to point out the effects of different Traffic Engineering functions on the load balancing into the GMPLS network.
